BACKGROUND

The U.S. Navy's Mobile Inshore Undersea Warfare (MIUW) system is an upgrade program for the Naval Reserves that provides enhanced surveillance and communication capabilities for port security, harbor defense, and the coastal warfare mission. This system requires a video camera and originally used a black and white camera. SPAWAR Systems Center, San Diego (SSC San Diego) upgraded to a color camera for better target detection and identification. For ease of integration, the color system needed to be totally compatible with the original system without requiring changes to hardware or software. After determining that no commercial off-the-shelf products were available that were compatible with the old software, modification of a product was considered. The video camera manufacturer offered to modify the camera for a fee. SSC San Diego determined that it would be more cost effective for the Navy to design and install a basic interface board in the off-the-shelf camera assembly.

This report describes the Video Imaging System (VIS) interface board that was designed by SSC San Diego and deployed in MIUW cameras.

BOARD REQUIREMENTS

The VIS interface board is inserted between the camera and the MIUW computer. The MIUW computer uses an RS-422 interface to issue commands in a format peculiar to the original black and white camera. These commands control camera power, zoom, focus, and iris. However, current camera interface command formats bear little resemblance to those used in the original MIUW camera assembly. Therefore, the board must translate the commands. The board must also interpret lens and power commands and include switches for these functions.

The camera requires lens feedback. This function requires a hardware solution apart from the camera, since no cameras provide a zoom/focus motor and preset interfaces. The hardware solution must read zoom and focus motor positions and send the information back to the interface.

The MIUW application must remotely alter iris settings through the serial interface. Some cameras offer a video output that automatically controls the iris. For remote control, two options are available. Either intercept the signal and modify it, or command the camera to change the signal. The first option requires hardware.

VIDEO IMAGING SYSTEM (VIS) INTERFACE BOARD

The VIS interface board provides wide flexibility in the camera interface. It employs a Siemens version of the popular 8051 type of microcontroller that has two Universal Asynchronous Receiver-Transmitter (UART) serial interfaces so it can communicate simultaneously with the user and a digital camera. This allows translation of commands from one command set to another so the interface can be made compatible with any digital camera with a serial interface and any user command set.

This board includes relays for controlling the zoom and focus motors of the lens and for turning the camera power on and off.

Firmware is stored in non-volatile flash, electrically erasable programmable read only memory (EEPROM) and modified remotely. This is accomplished by logic that switches the microcontroller to run out of volatile random access memory (RAM) during reprogramming.

The microcontroller contains an analog-to-digital converter for zoom feedback and focus settings.

If fully populated, this board uses a video frequency, multiplying digital-to-analog converter (MDAC) to modulate the automatic iris feedback for controlling the relative iris position. This enables the user to control the feedback loop to increase or decrease the light gathered by the lens without turning off the automatic iris function.

INTERFACE REQUIREMENTS

HARDWARE

The board must interface with the MIUW Interface Processor (IP), the camera, and the lens. Connector designations in this section refer to the board schematic. Figure 1 shows a schematic of the VIS Controller Board. Table 1 is the parts list.

Power is supplied to the board through a 2-pin connector (J1) and is nominally 12 volts DC. Anything from 7 to 15 volts will work, although 12 volts should be maintained for consistent zoom timing.

The camera and interface protocol (IP) serial interfaces are RS-422 standard interfaces using 4-pin connectors (J5 and J9).

The lens zoom and focus require a positive voltage to zoom or focus in one direction and a negative voltage to zoom or focus in the other direction. The 12 volts DC is routed to them through combinations of six relays and 3-pin connector J3 to enable a single supply to apply positive or negative voltage to either motor. Note that it is important to isolate the motors from ground for this configuration.

Preset potentiometers provide zoom and focus position feedback. Ground and 5 volts are provided, and wiper voltages are read through a 4-pin connector, J8.

Camera power uses a separate 12-volt supply that this board must control. The power comes into this board through a 2-pin connector, J2, and passes out to the camera through a 2-pin connector, J4. A relay on the board switches power on or off.

* IMPORTANT: The Flash EPROM and PAL (U15 and U16) must be programmed before installation!

SOFTWARE

The camera software interface is described in the Cohu “Installation and Operation Instructions” document for the “Model 3500 DSP Interline Transfer Color Camera.” The interface to the MIUW computer, also referred to as the Interface Processor or IP, VIS Interface Design Document (IDD) as follows:

VIS IDD November 22, 1998

1.0 Physical Connections.

4 wire (plus ground) RS422, full duplex

9600 baud, 8 bits data, one stop bit, no parity

2.0 Message Formatting.

2.1 Computer to VIS

Messages sent from the IP computer to the VIS camera are always formatted as follows:

STX (0xF8) Start of Transmission

Camera # Number of Selected Camera (0x01 always)

Camera command and data

Checksum byte

The checksum is calculated in a strange way. It is computed by performing an exclusive 'OR' of all the bytes in the message, following the STX character, and storing only the lower

nybble (lower 4 bits) of that value, with the most significant bit set. The following C code shows the method the VIS camera calculates the checksum byte:

```
Calc_checksum(unsigned char *ptr, count)
{
    int ii, xx;

    xx = 0;
    for(ii = 0; ii < count + 1; ii++) {
        xx ^= ptr[ii];
    }
    *ptr[ii] = 0x80 | (xx & 0x0F);
}
```

When a valid message is received at either the VIS or MSP, the receiver responds with an 'ACK' character (0x06). If a message is detected with a bad checksum or other error, the receiver responds with a NACK (0x15). This response precedes any response to the received message (i.e., the ACK is sent before the response to a status request, for example).

2.2 Camera Commands used by MSP Software

Toggle commands are two character commands that toggle the selected feature in the camera.

'LP' - Toggle Power
'LM' - Toggle Autoliris

Iris Open/Close/Stop commands are sent to cause the camera to open or close the iris. These are sent only if not in auto iris mode:

'IO' - Iris Open
'IS' - Iris Stop
'IC' - Iris Close

Status Inquiry commands are sent periodically. These are used to keep the MSP software up to date on the lens positions and other states. The 'On Line' indicates the fact that status messages are being received by the MSP indicator on the MSP VIS control panel.

'L?' - Request a 'Latch Status'
'V?' - Request a Lens Position Status

To set the lens zoom position and focus position, the following command is sent:

'v' - Lens Position Request. This is followed by six bytes. The first three bytes represent the zoom position, the last three bytes is the focus position. These position values

represent a 12-bit range from 0 to 4095. 4095 represents max zoom (smallest field of view) and focus to nearest range. The position is encoded four bits at a time, most significant bits first, each 'OR'd with the value 0 x 30. The following code illustrates creating a lens position message:

```
*ptr++ = 'V';
*ptr++ = ((zoompos & 0x0F00) >> 8) | 0x30;
*ptr++ = ((zoompos & 0x00F0) >> 4) | 0x30;
*ptr++ = (zoompos & 0x000F) | 0x30;
*ptr++ = ((focuspos & 0x0F00) >> 8) | 0x30;
*ptr++ = ((focuspos & 0x00F0) >> 4) | 0x30;
*ptr++ = (focuspos & 0x000F) | 0x30;
```

2.2 VIS to Computer

VIS messages are formatted exactly as described for MSP messages to the VIS. The MSP software decodes the following VIS messages.

'L' - Latch Status. Three bytes of status follow, with only the first byte being decoded. The lower nybble is decoded as follows:

Bit 0 – Iris Status. If 1, iris is manual, if 0, iris is automatic.

Bit 1 – Camera Power. If 1, camera is powered. If 0, camera is off.

The other bits and bytes are ignored.

'V' - Lens Status. Six bytes follow, formatted exactly as the lens position command.

HARDWARE DESIGN

The first concern in designing the board was keeping the design simple to minimize components and keep the board small enough to fit in a 4-inch camera housing, if desired. The Siemens microcontroller contains two UART serial interfaces and an analog-to-digital converter with eight multiplexed inputs. Having these features integrated into the microcontroller chip simplifies the board design and reduces the chip count.

Firmware for the microcontroller is contained on a Flash EEPROM chip (AMD AM29F010). During use, the firmware is copied to a RAM chip (Hitachi HM62256) and execution takes place out of the RAM. The 8051 microcontroller uses a "Harvard Architecture," which means that the program and data memory share the same address space. Therefore, the board uses a programmable logic array (PAL) to control which chip is mapped as program and which is mapped as data memory. This allows the Flash ROM to be reprogrammed by the microcontroller under remote control. The advantage of this arrangement is that the firmware can be easily modified with no disassembly of hardware. The disadvantage is that it requires a RAM chip and a PAL and added software complexity.

A 74HCT573 octal latch provides address latching for memory access. This is required since the microcontroller multiplexes the data and lower address signals onto eight pins.

Another 74HCT573 octal latch is used as a buffer between the microcontroller digital output pins and the relay inputs. The relays are solid state International Rectifier PVN012 optocoupled AC/DC relays. Two relays are used for each of the three pins: Zoom, Focus, and Common. One of the two relays can connect the pin to ground, and the other to +12 volts. This configuration allows a single +12-volt supply to provide positive or negative voltage to drive the zoom or focus motors. It is important to note that this will only work if the motors are isolated from ground.

A seventh PVN012 relay is dedicated to controlling camera power.

Two Maxim MAX3081 interface chips convert serial interface (UART) signals at the microcontroller to RS-422 signals at the camera and IP.

A UA7805, standard, 3-pin, 5-volt regulator provides logic power. An 11.059-MHz crystal for the system clock ensures that the appropriate serial interface frequency can be derived. A 33-microfarad capacitor at the microcontroller reset pin provides a solid power-up reset.

An optional feature is enabled when an Analog Devices AD8320 video multiplying digital-to-analog converter (MDAC) is installed. With this device, the amplitude-modulated video signal from the camera controlling the lens iris can be increased or decreased to open or close the iris. This is considered optional, because after the first board was built and tested for MIUW, it was determined that Cohu had changed their camera design to use a pulse-width-modulated video signal instead of an amplitude-modulated signal. This feature was not installed on subsequent boards. Instead, direct camera commands are issued to alter picture brightness. This produces the same results, but uses the camera digital signal processor.

Also optional on the board are five light emitting diodes (LEDs). These are used in testing and debugging the board. As configured in the schematic, the LEDs indicate the following:

D1 – Red when camera power is turned on

D2 – Yellow when zooming in, green when zooming out, off otherwise

D3 – Yellow when focusing near, green when focusing far, off otherwise

D4 – Red anytime power is applied to board

D5 – Yellow when executing program out of RAM, green when executing out of high Flash memory, off otherwise

Note: The green and yellow of D2 and D3 may be reversed, depending on the lens motor wiring.

FLASH REPROGRAMMING

The software controls flash memory reprogramming. This section describes the signals and logic involved in the memory control on the board, for use by someone making software or hardware modifications to the board. For a description of the reprogramming procedure used for altering the first software version, see the section entitled **FLASH REPROGRAMMING PROCEDURE**.

When power is first applied, the RAM will be empty, so the microcontroller must execute the firmware in the flash memory. To reprogram the flash memory, the microcontroller must be executing firmware out of RAM and accessing the flash as data memory. Therefore, the hardware must de-select flash and select RAM by switching the chip control signals in the middle of an instruction execution, without causing an execution glitch.

To do this, the Program Store Enable (PSEN) signal, Read (RD) signal, and two controllable port pins generate Chip Select (CS)/Chip Enable (CE) signals, Output Enable (OE) signals and a high address (A16) signal. One of the controllable port pins (P3.5) is designated as the flash programming selector (PGM). The other (P3.4) is designated the A16 address bit, inverted for proper reset initialization.

The signal logic is described in the following subsections.

PAL INPUTS

The PGM pin (P3.5) is made active (low) to command the system to execute out of RAM.

The A16 pin (P3.4) is made active (low) to select high flash memory.

PAL inputs also include the microcontroller RD and PSEN signals.

PAL OUTPUTS

The OE outputs carry the RD and PSEN signals. If in flash programming mode (PGM is active), then the flash OE = RD and the RAM OE = PSEN. Otherwise, the opposite applies.

The CE/CS outputs carry the PSEN and its complement. If in flash programming mode, the RAM CS = PSEN and the flash CE = PSEN inverted. Otherwise the opposite applies.

The A16 output is the complement of the A16 input. Table 2 also lists PAL output information.

Table 2. PAL outputs.

PAL Outputs	Normal Mode (PGM Not Active)	Flash Programming Mode (PGM Active)
Flash OE	PSEN	RD
RAM OE	RD	PSEN
Flash CD	PSEN	PSEN complement
RAM CS	PSEN complement	PSEN
A16	A16_ input complement	A16_ input complement

For added protection from disaster during programming, only the higher part of the flash chip is reprogrammed. The lower part is reserved for the basic reprogramming software. In case of error in programming, the software will still be able to run out of lower memory to accept instructions to reprogram the higher memory.

For another approach to in-system flash programming, see the Siemens Semiconductors application note AP0821 “C5XX/80C5XX In-System FLASH Programming” on their CD-ROM entitled “8-bit and 16-bit Microcontrollers CD-ROM Edition 2.0, *Siemens Semiconductors*, November 1997.

FLASH REPROGRAMMING PROCEDURE

To reprogram flash memory, the board must be powered up and connected to a PC via a serial port. Since the board uses an RS-422 interface and most PCs only have RS-232 serial ports, a converter such as the Telebyte Model 231 must be inserted.

The commands for reprogramming the flash memory were designed to use the “WinBurner Flash Memory Burner” software version 1.0.18, produced by Automated Enterprises, LLC, Scott M. Olmsted, 760-942-1953. This program runs in Windows 95 and sends a file using a logical sequence of handshaking communication through the serial port. Selections required for this program are:

Com1, 9600 baud, then click on “Open”

Check the boxes for: Insert Start Field, Insert Length Byte, Insert Stop Field, Insert 1-byte Checksum, Length Includes Checksum

Start: F8

Command: 55 Erase

66 Record

77 End

Stop: 03

Select Erase Type: App 1

Ack: 06

File Name: c:\vis\vis\vis.hex {this reflects the location of the compiled code.}

All other boxes and fields are left blank.

After setting up the software as described, click on “Download” to reprogram the flash memory. These settings are likely to be different if later versions of the WinBurner software are used, since this is an early (alpha test?) version and the byte counts seem to be off by one. But, this version has been successfully used with these settings.

The sequence of bytes sent is:

Start (F8h)

Length (1 byte)

Command (55h or 66h or 77h)

Type (0 for boot sector or low flash addresses, 1 for application sector or high flash)

Stop (03h)

Checksum (1 byte)

The checksum is a simple modulo 100h sum of all preceding bytes.

SOFTWARE DESIGN

Firmware is required in two locations on this board. The microcontroller firmware is located in the Flash ROM. PAL firmware is located on the PAL chip.

The PAL firmware is quite simple and implements the algorithms defined in the flash reprogramming section above. Appendix A provides the PALASM source code.

The microcontroller firmware was derived from original code developed by Gary Perkins of MicroWare Technology, Inc., San Diego, California. The source code was written in C and assembly language.

The assembly language code contains subroutines for copying code from flash to RAM and subroutines for switching back and forth between executing out of flash and executing out of RAM.

The main C routines are in the “Ric.c” file. These control the major functions as well as various minor functions.

The “Flash.c” file contains the routines for reprogramming the flash memory, putting out signals and commands to erase and reprogram.

The “Hostmsg.c” file contains routines which handle commands received from the IP serial port.

The “Ricisr.c” file contains the interrupt subroutines.

Files required for code compilation are:

C source code:

Ric.c

Flash.c

Hostmsg.c

Ricisr.c

Ric.h

Proto.h

Ricglob.h

Assembly language source code:

Ricasm.a51

Visboot.m51

Utility file:

M.bat

Appendix B provides printouts of the code.

SOFTWARE DEVELOPMENT TOOLS

The 8051 development tools chosen were Keil Software CA51 V5.2 Compiler Kit, comprising a C compiler and an 8051 assembler.

The PAL development tool used was a PALASM4 Ver 1.5 compiler, available as freeware from Lattice Semiconductor/Vantis at <http://www.latticesemi.com>.

FLASH MEMORY CHIP PROGRAMMING PROCEDURE

Although any compatible programmer can be used, the following is a procedure for using the Advin Systems, Inc. Pilot-U40. Filenames and directories may vary, but this procedure is based on the original computer configuration. If the software is modified, the checksum will be different.

1. Connect the Pilot-U40 to computer parallel port and apply power.
2. Execute program “spee.exe” in the Advin directory.
3. Set device to AMD 29F010.
4. Set filename to c:\vis\vis\vis.hex
5. Load file into buffer and program chip using menu commands.
6. Verify that checksum is 7C46.

PAL PROGRAMMING PROCEDURE

Although any compatible programmer can be used, the following is a procedure for using the Advin Systems, Inc. Pilot-U40. Filenames and directories may vary, but this procedure is based on the original computer configuration.

1. Connect the Pilot-U40 to computer parallel port and apply power.
2. Execute program “spgal.exe” in the Advin directory.
3. Select AMD/MMI PALCE16V8 as the device type.
4. Set filename to c:\advin\palasm\visfil~1\vis.jed
5. Load file into buffer and program chip using menu commands.

6. Verify that checksum is 3475.

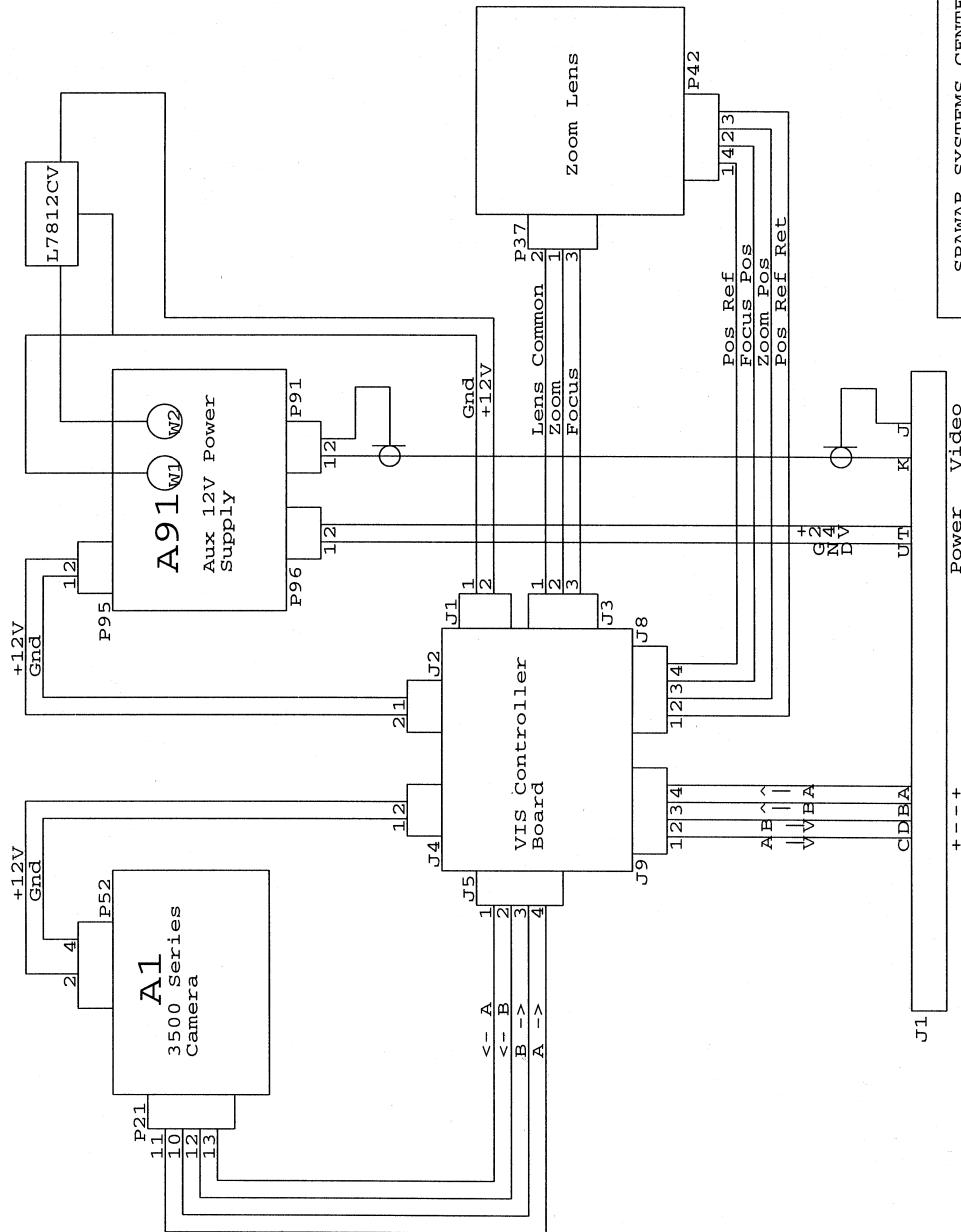

MIUW-SPECIFIC DETAILS

For the MIUW application, the Cohu Model 3522 color video DSP camera with engineering revision ER4565HN (Cohu's internal number) is used. This uses the Cohu Model 3522-1000 DSP inter-line transfer CCD color camera with a ½-inch sensor, NTSC compatibility, and a 12-volt DC supply. The lens is the Cohu "Model P10K," 10X, F1.8, 16 to 160 mm, with zoom and focus presets. Also included is a 2X range extender.

Figure 2 shows the wiring of the board to the camera.

For details of the first procurement, see contract N66001-99-C-0034.

Notes:
 A81, Zoom Lens Driver Board required but not shown.
 This diagram only shows those connections related to the VIS Controller Board.
 All other pins on J1 are unused. The heater must be connected to pins T and U.

SPAWAR SYSTEMS CENTER, SAN DIEGO, D372	
Title	VIS Controller Board Wiring Diagram
Size	Document Number
A	
Date:	May 27, 1999 Sheet 1 of 1

Figure 2. VIS Controller Board wiring diagram.

DRAWINGS

For reference, figures 3 through 7 show the printed wiring board layout drawings. There are two jumpers required on the board and one area of difficulty the manufacturer had in populating the boards using automatic techniques.

The printed wiring board requires the following two jumpers to match the schematic:

1. U14 pin 36 (currently open) to U9 pin 11
2. U14 pin 67 (currently open) to GND (the nearest C20 pad)

When populating the boards, carefully inspect the solder joints at the points that have feed-through holes reducing the pad size. Depending on the tolerances used in the etching process, the pad size may be very small, and it may be necessary to add solder after the automated soldering operation. The pads affected are:

U1 pin 2
U2 pin 5
U3 pin 5
U6 pin 5
U10 pin 14
U12 pins 1 and 10
U17 pin 4

LEDa = /A16_      ; LED will be off when running in low FLASH, or on in
LEDb = /PGM_      ; green or yellow, indicating whether running in high
                  ; FLASH or low RAM.

; EXPLANATION OF LOGIC
; "Program Store Enable" (PSEN_) is active when reading external
; program memory. It is routed to Flash when Program mode is not
; selected (PGM_ is high) and to RAM when Program mode is
; selected (PGM_ is low).

; RD_ is routed to RAM_OE_ when Program mode is selected
; (PGM_ is low) and FLASH_OE_ when Program mode is not selected.

; PSEN_ is inverted and routed to RAM_CS_ when Program mode is
; selected (PGM_ is low) and FLASH_CE_ when Program mode is
; not selected.
